Abstract

Purpose In the first 24 h post-intervertebral disc (IVD) trauma, up to 75 % cell death has been reported. In addition, burst fractures cause post-traumatic disc degeneration by elevated pro-apoptotic and pro-inflammatory gene transcription. Moreover, some patients have pre-trauma degenerative disc disease. The aim of the study was to assess histological changes and cell-death over a time period of up to 1 year caused by mechanical and structural factors.

Methods 116 anterior portions of IVDs of the cervical spine were studied histologically by light microscopy and ultrastructurally by transmission electron microscopy (TEM). The group was investigated with regard to three main parameters: fracture mechanism (compressive vs. tensile/shear loads), degeneration grade (low vs. high) and endplate fracture (with vs. without). Disc architecture (e.g. ruptures) was studied histologically. Cell morphology was examined ultrastructurally to quantify cell-death, healthy

and balloon cells. According to ultrastructural observations, two time-groups (up to 6 days vs. later) were established. Statistical analyses were carried out within and between time-groups.

Results Histological changes were obvious in the annulus fibrosus where ruptures with haematoma were replaced by granulation tissue. Significant differences in cell-death were seen in the first few days due to different loads. In contrast to the more degenerated segments, low degenerated ones revealed significantly less cell death with time post-trauma. Interestingly, no difference was found between groups after the sixth day. Cell-death (mean 44 % for all investigated groups) remained high after day 6 post-trauma.

Conclusion IVDs retrieved from low grade degenerated segments revealed a significant recovery, with less cell-death and a partially restored disc matrix, although cell-death remained high. Long-term clinical studies of stabilized segments arising from different fracture mechanisms are required.

Introduction

The integrity of the intervertebral disc can be dramatically diminished by traumatic injury or degenerative disc disease (DDD). Disc degeneration is typified histologically by changes at the cellular level [1]. Increased cell proliferation and cell-cluster formation occur, as well as increased cell-death. Gross matrix changes include lamellar disorganization and fissures [1].

Böhler defined a radiological loss of disc height after spinal fracture as a disrupted intervertebral disc [2]. He described conservatively treated spine fracture healing by osteophytes that bridged towards the adjacent vertebrae. Smith and Wamsley reported on subsequent changes which occurred after incision of rabbit discs, with healing of the superficial fibres by proliferating reactions. Closure of the wound by an active fibrous tissue reaction was for the most completed after 4 weeks. These became calcified and before calcification was completed ossification occurred. While the outer annulus fibrosus healed, the inner annulus fibrosus failed to heal [3]. In an ovine model, nucleus pulposus (NP) 5 mm deep incised discs showed significant matrix changes with loss of proteoglycans and collagens 8 months post-operatively and demonstrated a decrease in disc height and marked degeneration of the NP [4]. An incision of 6 × 20 mm caused vessel ingrowths around the annular lesion, cell cloning in the iAF and loss of NP aggrecan and disc height [5]. Moreover, profound post-traumatic disc degeneration was seen when endplate lesions and vertebral fractures were involved. An in vitro rabbit burst fracture trauma model induced programmed cell death by apoptosis in endplate-disc specimens, with caspase-3/7 levels still elevated up to 28 days [6, 7]. Consistent with investigations in mouse tails, apoptosis is dependent on the magnitude and duration of spinal loading [8]. Chondroptosis was introduced by Roach as a variant of apoptotic cell death in chondrocytes [9]. Chondroptosis involves an increase in the endoplasmic reticulum and the Golgi apparatus, as well as autophagic vacuoles which lead to complete self-destruction of the chondrocyte [9]. Highest numbers of apoptotic and chondroptotic cells were found post compressive fractures, up to 3 days post-trauma, in human IVDs [10]. Moreover, the response of disc cells in patients with different types of trauma (compression versus more tensile and shear loads) resulted in significant differences in disc cell morphologies [10]. Healthy cells were a rarity, with the majority of cells

appearing necrotic. A novel disc cell morphology, the balloon cell, could be described post compression trauma. These cells display a homogeneous euchromatin-rich nucleus, enveloped by an osmiophilic nucleus membrane [10]. Cytoplasmic changes varied from mainly intact membrane structures of organelles to severe necrotic changes, with a complete loss of membranes and organelles [10]. In contrast, discs with the pathology of degeneration and herniation presented less apoptosis/chondroptosis [11]. Moreover, in low grade degenerated herniated discs (DG II/III), the balloon cell was routinely found in the iAF and presented itself viable, with the ability to proliferate into clusters [11]. Such nucleus morphologies are seen in many tissues of high activity, e.g., plasma cells of Multiple Myeloma [12]. However, the potential pathogenic role of the balloon cell in different disc pathologies has yet to be established.

The involvement of a pathologically altered IVD, where high degeneration grades (IV/V) are radiologically observed and degenerative disc disease must be expected, leads us to hypothesize different cell responses in fractured segments of lower and higher degeneration grades (DG). Thus, spine fractures were classified into different fracture types (compressive vs. less compressive with more tensile and shear loads) and investigated here with regard to their degeneration grades. The objectives of this study were to assess changes in the different groups with time post-trauma, microscopically and ultrastructurally.

Materials and methods

One hundred and sixteen anterior portions of ninety-five human injured cervical segments were investigated histologically ($n = 113$) and ultrastructurally ($n = 111$). Patients were injured through car accidents, accidents at work or home and during leisure. Fractures investigated in this study are high-energy injuries which are characterized by either compressive load and/or tensile and shear loads, combined with dislocation of bony structures and disc material. A delay in surgery was seen in multiple trauma injuries and due to transport from another hospital to our spine unit. Some fractures were primarily classified as uncomplicated fractures, presenting no dislocation or malposition and no neurological deficits, and treated conservatively. In some fractures due to secondary dislocation, increasing malposition and persisting pain, the treatment plan was changed to a surgical treatment. Mean age of the investigated patient group was 42 years (16–80 years). According to ultrastructural observations this group was split into two time-groups: 0–5 days post-trauma ($n = 59$) and 6 days to 1 year post-trauma ($n = 57$) (Tables 1, 2).

The study and recruitment procedures were approved by the Ethics Committee, Medical University of Innsbruck (Ethics committee: UN 1052; UN 1653; UN 3849). All participants gave written informed consent after a full explanation of study procedures.

Disc samples were removed during routine surgery (anterior approach) following trauma of the cervical spine (C2/3-C7/Th1). Samples were prepared and immediately dissected into three portions from the longitudinal ligament (LL) towards the NP. These were processed for light and transmission electron microscopy.

Imaging Due to pathomorphological criteria, fractures were classified radiologically (X-ray, CT scans) according to Magerl's classification [13]. These are either (A) compression injury, (B1, 2) flexion combined with compression in the anterior disc portion and (B3) extension or (C) rotation injury. The predominating load (more compression or more tensile and shear loads) was evaluated for the anterior disc portion of the investigated segment. Two groups were assessed: fracture group 1 with more compressive loads (A-, B1-, B2- and C-fractures with cranial trauma to the head; $n = 78$) and fracture group 2 with less compression, more tensile and shear loads (B3- and C-fractures; $n = 38$). For all injured segments the degeneration grade was scored radiologically (X-ray, CT scans) [14]. Degeneration grades I-III were defined as low (DG1: $n = 83$) and grades IV-V as high (DG2: $n = 33$). The fracture groups and degeneration groups were investigated within the different time-groups and both time-groups were compared to each other. To address endplate fractures two groups (only low grade degenerated segments were included) were established: EP1 without endplate fracture and EP2 with endplate fracture. Four independent observers (2 traumatologists, 2 radiologists) examined all images; discrepancies in scores were solved by consensus opinion.

Histology Most samples included the anterior LL, the annulus fibrosus (AF) and the NP. These were fixed in 4 % paraformaldehyde, embedded in wax and stained with haematoxylin-eosin [15]. Parts of the samples were fixed in Schaffer solution, embedded in methyl methacrylate (MMC) and stained with Goldner's trichrome [15]. Resin blocks were cut at 4–6 μm thickness, whereas paraffin blocks at 8–10 μm . Sections were evaluated on a Leica DM 6000/DFC 480 using the image software IM500. Morphological features such as disc rupture, vessel ingrowth and cell cluster formations were noted. In addition, cell counts/ mm^2 were undertaken by photographing one representative field (oAF, iAF and NP) of view ($\times 10$ objective) of haematoxylin-eosin stained sections.

Ultrastructure Disc specimens destined for ultrastructural analysis were taken from the middle part of the

anterior portion containing the LL to the NP. These were dissected into 4 cubes (2–3 mm each; A-D). The samples were fixed in 2.5 % glutaraldehyde and post-fixed in 2 % osmium tetroxide. After embedding in Araldite, sections were treated with uranyl acetate and lead citrate [16]. Gold standard Sections (70–100 nm) were examined in a Zeiss EM 10 transmission electron microscope. Both matrix and cell morphologies were assessed. At least 25–60 cells were examined in each sample of the oAF, 20–50 in the iAF and 15–30 cells in the NP. Qualitative and quantitative analysis of disc cell death (apoptosis, chondroptosis and necrosis), balloon and healthy cells (Fig. 9a–f) were recorded using the following criteria:

- (a) *Necrotic cell* Loss of integrity of the cell membrane and/or the nuclear membrane, swelling and vacuolization of cell organelles and/or loss of organelle membranes [17, 18].
- (b) *Apoptotic cell* Cell shrinking and blebbing of the cell membrane; nuclear condensation (DNA), margination of chromatin and ruffling of the plasma membrane. Apoptotic bodies comprise cell organelles and/or nuclear material enclosed by an intact cell membrane [19–21].
- (c) *Chondroptotic cell* Patchy, condensed chromatin; increased endoplasmic reticulum and Golgi apparatus; autophagic vacuoles; blebbing of cytoplasmic materials/vesicles but no true apoptotic bodies according to the definition of Kerr [9].
- (d) *Balloon cell* A rounded homogeneous nucleus (euchromatin) surrounded by an osmiophilic dark nuclear envelope, frequently presenting a nucleolus. Various amounts of rough endoplasmic reticulum (rER), mitochondria and a Golgi apparatus observed [11].

Three independent observers (1 cell biologist, 2 traumatologists) examined all images; discrepancies were solved by consensus opinion.

Statistical analyses

Object characteristics were summarized in percentages as well as presented as median and interquartile range (IQR). Differences between two unpaired groups were assessed using the non-parametric Mann–Whitney U test. P values < 0.05 were considered statistically significant. Threshold analysis was performed using the Mann–Whitney U test and visualized by a scatterplot including a trend line using LOESS (Local regrESSion) smoothing with an 80 % span. Calculations were performed using SPSS version 20.0 (Armonk, NY, USA) and MedCalc version 15 (MedCalc Software, Ostend, Belgium).

Cervical fracture classification according to Magerl's system [13]

DG degeneration grade I–V [14], IVD intervertebral disc, LL anterior longitudinal ligament, oAF outer annulus fibrosus, iAF inner annulus fibrosus, NP nucleus pulposus, granul. tissue granulation tissue, “–” not available, “+” compression in the anterior portion of the IVD

Fig. 1 a Scatter plot of cell-death in the first 8 days post-trauma (pt) in percent. Cell-death includes mean values of investigated cell death by necrosis, chondroptosis and apoptosis in the anterior portion of the disc post-trauma. The line indicates a trend line using LOcal regrESSion (LOESS) scatter plot smoothing (80 % span). **b** Proportions of cell-death by necrosis, chondroptosis and apoptosis in the first 8 days post-trauma of low grade degenerated intervertebral discs

Results

Ultrastructural investigations revealed considerable differences between day 4 and 6 post-trauma. Whereas micro-ruptures and a disorganized fibril structure were seen in the outer annulus regions in the first days post-trauma, matrix was largely restored with parallel fibrils and less micro-ruptures after the fifth day. Some recovery of disc cells was apparent, with less cell death and more healthy cells and reorganized fibril architecture. Cell proliferation was apparent after day 6. Statistical analyses of the first 8 days of low grade degenerated discs indicated a significant

change, to less cell death by necrosis, apoptosis and chondroptosis, after the third day of injury ($P = 0.016$) (Fig. 1a, b). In the two time groups established, (time-group 1 between 0 and 5 days post-trauma and time-group 2 after 6 days post-trauma), no significant difference was found in patients matched for age (Tables 1, 2).

Time-group 1

Imaging Patients with high degeneration grades presented ventral and/or dorsal osteophytes and changes in endplate with signs of severe osteochondrosis. This was not seen in

patients with low grade degenerated discs. A-fractures showed for the most part multiple endplate fractures, which were rarely seen in B- and C-fractures. The alignment of the cervical spine was disturbed (Fig. 2a, c). Twenty-three out of forty-seven low-grade degenerated segments displayed no endplate fracture.

Histology In the first days post-trauma, disc architecture was destroyed, with ruptures with in-bleeding in all compartments of the disc. The normal laminar structure was replaced by radial ruptures in compression fractures. In contrast, C-fractures showed ruptures along the different laminae in the AF (Fig. 3a). Whereas fractures with a low degeneration grade presented a minor number of small cluster formations in the iAF and the NP, more and greater clusters were seen in specimens from patients presenting a higher degeneration grade (Table 1). Some blood vessel ingrowth was apparent in both degeneration groups, coming from the LL and reaching the outer edges of the oAF. Hardly any granulation tissue was seen in discs with high grade degeneration (Fig. 3c). Mean cell count was higher in the AF than in the NP for both fracture groups and degeneration groups (Fig. 4). Significantly higher values of cell counts were present in specimens with high degeneration grades of less compressive fractures, compared to more compressive ones (iAF $P = 0.007$) (Table 3).

Ultrastructure The percentages of different cell morphologies are presented in Fig. 5. Destroyed matrix and damaged cells, including cell debris, were found in the first days post-trauma. Up to 100 % cell-death was apparent in some parts of the injured discs (Table 1). When comparing both *fracture groups*, significantly more apoptosis was seen in the iAF ($P = 0.004$) in compression fractures of low degeneration grade, whereas chondroptosis presented the highest values in the oAF ($P = 0.003$) and NP ($P = 0.038$) (Table 3); significantly less necrosis was seen in the iAF ($P = 0.001$) and NP ($P = 0.016$) than in fractures with more tensile and shear loads. Balloon cells developed a homogeneous nucleus, sometimes a nucleolus and shortly after trauma, some necrotic features in the cell matrix. Significantly more balloon cells were found after compression trauma in the iAF and NP ($P = 0.001$) of discs with minor degeneration than in less compressive fractures.

Comparing the *degeneration groups*, minor differences were seen: for the compression group, the iAF in discs with low degeneration grade presented more apoptosis ($P = 0.028$); less compressive fractures (low degeneration grade) presented significantly more necrosis (NP $P = 0.029$) than discs with a high degeneration grade.

Comparing groups with and without *endplate fracture* and low degeneration grade, significantly more apoptotic cells (iAF $P = 0.019$) and more chondroptotic cells (NP $P = 0.005$) were seen when the endplate was fractured,

whereas lesions without endplate fracture showed more necrotic cells (iAF $P = 0.01$; NP $P = 0.02$).

Time-group 2

Imaging Fractures were healed, for the most, 2 months post-trauma with minor signs of endplate sclerosis. Twenty-six out of thirty-five low grade degenerated segments displayed no endplate fractures (Fig. 2b, d).

Histology Vessel ingrowth and granulation tissue were found along the ruptures with time post-trauma in discs with a low degeneration grade, whereas in higher degeneration grades, granulation tissue was all over the AF (Fig. 3b, d; Table 2). More and greater cluster formations were seen in discs of higher degeneration grades. A significant difference in cell count (Fig. 6) was seen comparing the different degeneration grades. An increased number of total cells could be counted in the oAF ($P = 0.013$) when degeneration grade and compression loads were high. Comparing both *fracture groups* with low grade degeneration, no differences were apparent. Significantly more cells were counted post-compression in highly degenerated discs (oAF $P = 0.029$) (Table 3).

Ultrastructure Less cell debris and a largely restored matrix were seen in this time-group. Vessel ingrowth occurred as early as 7 days post trauma with endothelial cells coming from the LL into the oAF (Fig. 9g–i). The percentages of the different cell morphologies are shown in Fig. 7.

No differences comparing both *fracture groups* were seen in low or high grade degenerated discs (Table 3). Interestingly, this time-group presented no differences comparing both *degeneration groups* for compression and less compressive fractures. Low grade degenerated segments with *endplate fractures* did not show differences to lesions without endplate fractures (Fig. 8).

Time-group 1 versus time-group 2

Cell proliferation was found in all compartments due to compression load irrespective of low or high grade degeneration (Table 4). Interestingly, less compressive fractures (low grade degeneration) presented more cell proliferation in the oAF ($P = 0.041$).

Compression fractures in discs with low grade degeneration revealed significantly less apoptosis (iAF $P = 0.005$; NP $P = 0.013$), less chondroptosis (oAF $P = 0.031$) and necrosis (oAF $P = 0.002$; iAF $P = 0.045$) with time post-trauma. In contrast, *less compression fractures* (low grade degeneration) revealed no difference in apoptosis/chondroptosis, and less necrosis in

Fig. 2 CT scans illustrating instances of cervical rotation fractures: **a** Patient No 37: rotational anterior dislocation with articular process fracture 2 days post-trauma. *Inset* image presents posterior right fractured articular process. **b** Patient No 54: rotational flexion subluxation with unilateral fracture of the articular process plus type A-fracture 317 days post-trauma with healed anterior compression of

the vertebra. *Inset* image presents posterior unilateral healed articular process. **c** Patient No 23: flexion-distraction injury with rotational anterior dislocation 0 days post-trauma. *Inset* image presents posterior unilateral dislocation. **d** Patient No 34: flexion-distraction injury with rotational anterior dislocation 32 days post-trauma. *Inset* image presents posterior unilateral healed articular process

all compartments (oAF $P = 0.005$; iAF $P = 0.002$; NP $P = 0.005$). Nevertheless, more healthy cells were seen in all compartments in both *fracture groups* and low grade degenerative discs comparing both time groups (Figs. 5, 7).

With higher *degeneration grades* only the iAF displayed less necrosis ($P = 0.043$) and more healthy cells ($P = 0.037$) in compression fractures. No further differences for degeneration grade IV and V discs were found.

Comparing low grade degenerated segments with and without *endplate fracture*, those displaying endplate fractures showed significant differences, having less apoptosis (iAF $P = 0.02$) and less necrosis (oAF $P = 0.002$). In contrast, those without endplate fractures revealed less necrosis in all compartments (oAF $P = 0.003$; iAF $P \leq 0.001$; NP $P = 0.001$). Even though both groups presented more healthy cells (EP1: oAF $P = 0.002$; iAF $P \leq 0.001$; NP $P = 0.001$. EP2: oAF $P = 0.002$) with time post-

trauma, some cell-death by apoptosis/chondroptosis and necrosis remained in all investigated groups (Figs. 8, 9d–f).

Overall, cell-death was reduced significantly in most compartments in low grade degenerated discs, but remained high with a median of 43 % (35, 58) for all groups in the oAF [iAF 38 % (29, 52), NP 44 % (31, 68)], similar to high grade degenerated discs.

Discussion

This study reports on 116 post-trauma discs, classified into different groups by injury type and degeneration grade. Acute trauma differed in both fracture groups by either more compression and/or more tensile and shear loads. Intervertebral discs with a low grade degeneration either represent a group of healthy, healthy aged discs, or pathological discs, e.g., an unknown DDD. For IVDs with higher degrees of degeneration, a DDD must be assumed.

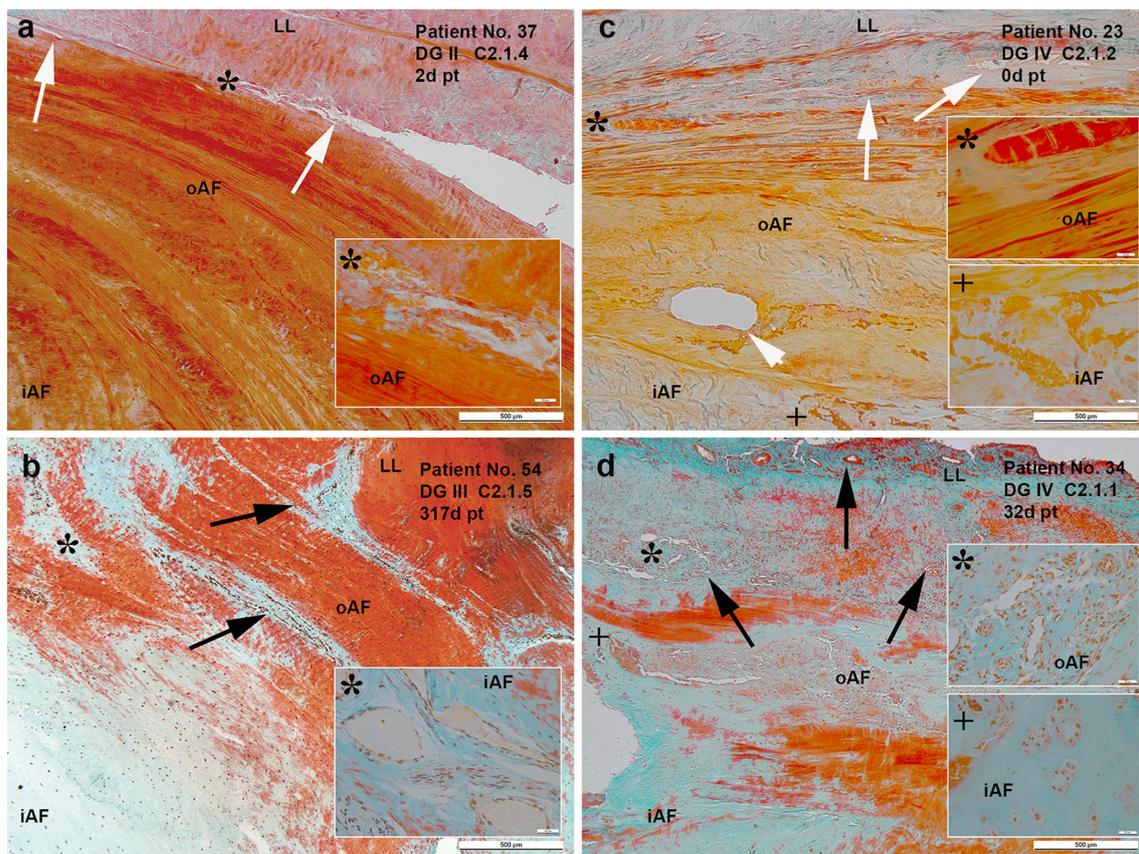

Fig. 3 Histological investigations of less compressive rotation fractures (corresponding to CT scans in Fig. 2). Goldner trichrome histology of MMC section presents the outer regions of the intervertebral disc (scale bar 500 µm). Asterisks/cross point out the location of higher magnifications (scale bars 20 µm). **a** Patient No. 37 demonstrating outer annular separation (white arrows). Inset image presents the annular rupture. **b** Patient No. 54 ingrowth of granulation tissue along annular ruptures (black arrows). Inset image offers vessel ingrowths. **c** Patient No. 23 small outer annular ruptures (white

arrows) in a disorganized disc. Inset image (asterisk) presents a rupture containing haematoma; (small white arrow) points out an annular degenerative cyst. Inset image (Plus) shows small ruptures containing haematoma. **d** Patient No. 34 extensive ingrowth of granulation into and around annular ruptures (black arrows). Inset image (asterisk) shows vessel ingrowth surrounded by proliferating cells. Inset image (plus) presents huge cluster formations. Abbreviations used: LL longitudinal ligament, oAF outer annulus fibrosus, iAF inner annulus fibrosus, pt post trauma, DG degeneration grade

A limitation of this study might be that instability of an injured segment was not addressed.

High necrosis values were seen in the first days post-trauma and due to compression trauma, high values for apoptosis/chondroptosis with minor differences. The response in the first days post-trauma to compression trauma was almost independent of degeneration grades. For both fracture groups cell-death changed significantly between the investigated time groups, especially in discs with a low degeneration grade. This was not seen in highly degenerated discs. It must be assumed that highly degenerated discs have higher necrosis values prior to trauma [1, 11]. The pathology of degeneration and herniation presented high necrosis values in all compartments of the disc and was similar for all degeneration grades (II–V) [11].

A recent publication revealed lactate dehydrogenase activity, as a marker for necrotic cell death, to be

increased up to the third day post-burst fractures in discs of healthy rabbits. Control levels were reached around the fifth day, whereas apoptotic cell death was elevated up to 28 days post-trauma [22]. This was shown for burst fractures, where a structural perturbation of the endplate/IVD was found [22]. Equienergetic loading or nuclear depressurization did not lead to the same results [22]. Our study revealed a significant decrease in cell-death by apoptosis with time post-trauma in the iAF and the NP in low grade degenerated discs, whereas chondroptotic cell death was reduced in the oAF, but remained in some parts of the IVD. Traumatized segments with or without endplate fractures cannot easily be compared between our study and that of Dudli et al. as the mechanism of fractures differed [22]. Nevertheless, fractures without endplate fracture revealed significantly less necrosis and more healthy cells with time post-trauma, but did not differ

compared to those with endplate fracture. This might be caused by prolonged malpositioning with abnormal loads or instability caused by fracture and dislocation of dorsal structures.

Investigations in healthy bovine discs, where discs were traumatized by an impact loading, revealed similar disc cell morphologies and cell-death as found in burst fractures (DGI+II) up to 5 days post-trauma in human cervical

spines [23]. Balloon cells were found within the AF of loaded bovine discs within a distinct range of absorbed energy [23]. It may be hypothesized that increased numbers of balloon cells, especially in the NP of minor degenerated discs, could have additional DDD. At the moment, it is

impossible to distinguish balloon cells morphologically as originating from compression or a degenerative disc disease. Battie et al. were able to show with the twin study, that more than 70 % of disc degeneration is based on a genetic influence [24]. Only minor influence was found as a

result of ageing and physical loading [24]. Although others report on similar processes such as fragmentation of certain SLRP (small leucine-rich proteoglycans) core proteins (e.g., biglycans, lumican) in pathological tissues from patients with scoliosis, DDD and herniations, which are important for organization of collagen fibres and hence the structure of the extracellular matrix, the origin of these pathologies is different [25]. Moreover, there is evidence

that these are involved in regulating inflammatory pathways [25]. Dudli et al. reported on up-regulation of matrix remodelling genes being stable within 28 days following burst fractures in rabbits [26]. Burst fractures caused a strong up-regulation of pro-inflammatory and a moderate up-regulation of pro-apoptotic genes, with all transcription levels back to control levels after 4 weeks [26]. This group, furthermore, found endplate fracture to be the key

aetiological factor for post-traumatic disc degeneration. Nevertheless, compression and/or tensile and shear loads did not disturb the remodelling phase, nor did an insufficient nutrient supply by sclerotic endplates [27]. Moreover, post-trauma studies revealed Caspase 3/7 to be elevated by an increase of the FAS receptor which was only found in post-trauma discs but not in degenerated discs. Up-regulation of the tumour necrosis factor (TNF) receptor was found in both study groups, in post-trauma patients and those with a degenerative disc disease [28, 29]. However, clinical and radiological investigations of traumatic thoracolumbar fractures with endplate fracture, as seen in burst fractures, report on favourable outcomes after stabilization and balloon-assisted endplate reduction up to 6 years post-trauma [30].

Investigations on scoliotic discs of AIS (adolescent idiopathic scoliosis) present an opportunity to study the effects of long-term loading, which is known to result in severely degenerated segments of the affected parts of the spine in elderly patients [31]. The different loading impact has tremendous effects on the IVD and its cells. High numbers of necrotic cells were found on both sides in all compartments, whereas balloon cells were mostly seen on the concave side of these apical discs [32], where more compressive load is expected. Other groups found

decreasing rates of cell-death in segments adjacent to apical discs [33]. Dynamic as well as static overload induced early degenerative processes and cell-death in caprine IVDs. Inflammatory related genes were up-regulated [34]. Disruption of the NP and the posterior annulus was histologically obvious in both groups [34]. High mechanical strains promoted secretion of cytokine, inflammatory and neurotrophic factors in human IVD cells, which were associated with DDD [35]. Interestingly, the histology of scoliotic discs presented some vessel ingrowths, some ruptures, but no granulation tissue in this young patient group [32]. Nor did degenerated discs obtained from herniated cervical discs present any granulation tissue in the anterior portion at any degeneration grade, but some vessel ingrowths were surrounded by rare fibrocystic cell invasion [11]. Kokubo et al. described granulation tissue surrounding the hernia in degenerated discs [36]. However, granulation tissue was present in most discs after 3 weeks post-trauma, consistent with incision studies done by others [3, 5, 37]. Disturbance of nutrient pathways by increased sclerosis of the healing endplate may be suggested, and defective healing by granulation tissue resulting in decreased stability of the IVD [37]. As the turnover of disc matrix is very slow [38, 39], a collapse of low grade degenerated discs might appear some years

post-trauma [40, 41], especially in those with endplate fracture.

Conclusion

This paper is able to show differences in histology with time post-trauma, with granulation tissue ingrowth present in the outer injured regions of the disc and high cell death, mainly by necrosis. As disc lesions are

supposed to be similar in the cervical and thoracolumbar spine, the question remains whether reduction and stabilization of a fractured segment is enough to stop high cell-death, found to be similar in both degeneration groups with time post-trauma and independent of the different loads. The survival of an intervertebral disc with a higher degeneration grade and a reduced disc height is doubtful. Long-term clinical follow-up studies of stabilized segments of different fracture types are needed.
